Pb17Li is today a reference breeder material in diverse fusion R&D programs worldwide. Extracting dynamic and structural properties of liquid LiPb mixtures via molecular dynamics simulations, represent a crucial step for multiscale modeling efforts in order to understand the suitability of this compound for future Nuclear Fusion technologies. At present a Li-Pb cross potential is not available in the literature. Here we present our first results on the validation of two semi-empirical potentials for Li and Pb in liquid phase. Our results represent the establishment of a solid base as a previous but crucial step to implement a LiPb cross potential. Structural and thermodynamical analyses confirm that the implemented potentials for Li and Pb are realistic to simulate both elements in the liquid phase.

I. INTRODUCTION

One of the main issues in current Nuclear Fusion programs (particularly magnetic confinement fusion) is the problem of liquid metals breeder blanket behavior. The structural material, constituting the blanket should meet high-performance requirements because of extreme operating conditions. The experimental data available are still scarce and sometimes the experimental uncertainty is important. Therefore the knowledge of eutectic properties like optimal composition, physical and thermodynamical behavior or diffusion coefficients of tritium, are extremely necessary for current designs. In particular, the knowledge of the function linking the tritium concentration dissolved in liquid materials with the tritium partial pressure at a liquid/gas interface in equilibrium, \( C_T = f(P_T) \), is of basic importance because it directly impacts all functional properties of a blanket determining: tritium inventory, tritium permeation rate and tritium extraction efficiency. Nowadays, understanding the structure and behavior of this compound is therefore a real goal in fusion engineering and materials science.

The molecular dynamics (MD) study of liquid lithium and lead reported in this manuscript, is the first work in the literature testing the validity and the implementation of EAM potentials to model metals like Pb or Li in liquid phase. In addition, it represents the first step in order to develop a LiPb cross potential for classical MD simulations able to understand the physics underlying the properties of the eutectic mixture in working conditions of interest for Nuclear Fusion technology.

II. INTEREST OF Pb AND Li IN THE CONTEXT OF FUSION ENERGY

In different blanket concepts Li17Pb is foreseen as tritium breeder and neutron multiplier: in different blanket concepts, Helium Coolant Lithium-Lead (HCLL), Water Coolant Lithium Lead (WCLL), Dual Coolant (DCLL) etc being HCLL concept selected as EU Test Blanket Module (TBM) to be tested in ITER. Much experimental and theoretical work has been done in the past years, covering many aspects of compatibility between PbLi and its environment. Particularly, significant results have been achieved in the field of corrosion of steels, refractory metals and ceramic materials MHD effects etc. However despite of so many efforts PbLi-hydrogen isotope interaction and Tritium extraction technology are still critical issues.

Next table (Table I) compare some physical properties of lithium-lead eutectic alloy, namely Li17Pb or Li17Pb83, (the exact title his not been yet determined) with other possible breeding materials as pure lithium, fluor-lithium salts (Flibe) and other eutectics like Li20Sn80. Current studies point that LiPb has fairly good breeding properties and middle chemical activity. For instance, a clear advantage will be that tritium release would be just \( T_2 \) and/or HT instead of TF for example when using Flibe.

Importantly, only the order of the diffusivity is known, and dispersion in solubility results depending on the technique makes the database inadequate for design purposes. Some reason seems to be the strong dependence of tritium solubility with lithium concentration. This is one of the main reasons that make so important the exact determination of eutectic point in the LiPb system. (See figure 2).

III.A EAM potential for Li

In the case of Lithium, we decided to use the approach of D. Belashchenko\textsuperscript{10}. His description was appropriately implemented in LAMMPS format by homemade codes. Note that in our calculations, we found that the potential parameters are valid for calculating basic properties of lithium such as lattice constant, cohesive energy, density and heat capacity, when the cutoff distance is taken to be larger than 1.5\(a_0\) [third-nearest neighbor (NN)].

III.C Computational details

Samples for Pb and Li ranged in size from 10,000 up to 100,000 atoms. They were canonically generated, energy minimized and equilibrated. We have also tested possible size effects in our results and set up. For example, a Pb a sample of 5,000 atoms was checked to be equivalent to an equivalent one 10 times bigger in size. Periodic boundary conditions (PBC) were imposed to minimize surface and edge effects.

MD simulations were carried out using the parallel code LAMMPS\textsuperscript{9}. Integration algorithms of Verlet and RESPA were benchmarked. The integration time step used for the heating and equilibrating phases was 10\(^{-4}\) ps. In the production phase we used a dt of 10\(^{-4}\) - 10\(^{-5}\) ps and we always tested in both cases a proper convergence. Average length of simulation time in production stage (equilibrium) was around 50 ps.

Trajectories in the canonical ensemble (NVT) were generated after 5ps of heating by coupling our system to a Berendsen thermostat\textsuperscript{11}, and ulterior equilibration using a Nosé-Hoover chain\textsuperscript{12}.

IV. RESULTS. VALIDATION OF Li AND Pb EAM POTENTIALS

A solid model interatomic potential for MD simulations (EAM -type in our present case) must be able to provide a good representation of dynamics, thermodynamics and structural properties of the target material under conditions relevant for technology. In addition, in order to develop future cross potentials\textsuperscript{13} (PbLi, Pb-He, Li-T, etc) a set of very particular conditions must be fulfilled to give confidence at the base of the methodology using an effective representation in the EAM alloy composition dependent framework developed by A.Caro\textsuperscript{14}.

IV.A. Study Of Static Properties

As a first test, simple but critical, we have calculated the static properties, cohesive energy and lattice parameter, for Pb and Li at 0 K. Doing that we obtain the values represented in table II for Pb and Li respectively. Our values are in good agreement with the experimental data reported in the works of Brandes, Toloukian, Dewaele, and Xie.\textsuperscript{15-18}. Note that the experimental values reviewed from these works, are \(E_c\)(Pb) = -2.03; \(a\)(Pb)= 4.9095 and \(E_c\)(Li) = -1.63; \(a\)(Li) = 3.355.

</tbody>
</table>

TABLE II

Our agreement is not surprising, since the cohesive energy is one of the physical properties used to adjust the parameters that define the potential, in particular the atomic electron-density. The cohesive energy is a measure of the cohesion of the atoms and should be therefore comparable to the sublimation energy.

IV.B. Study Of Structural Properties

Structural order and distribution of particles within a fluid is frequently well described by the pair-correlation function \(g(r)\). This quantity is related to the probability of finding the center of a particle a given distance from the center of another particle. For short distances, this is related to how the particles are packed together. Therefore, it is a good magnitude to study if we want to be confident in our potential behavior.

It is defined as

\[
g(r) = \frac{1}{2\pi r^2} \left( \frac{\sum \sum \delta(r-r')}{N^2} - \frac{1}{N} \right)
\]

Our calculations using the previous mentioned versions of EAM potentials for Li and Pb, are in very good agreement with experimental results. As can be seen in Figure 3, the radial distribution function \(g(r)\) matches very well the experimental results reported by Y.Waseda\textsuperscript{19} in the liquid phase for both elements.

The graphs present a comparison of the radial distribution function of both Pb and Li at different
working temperatures of interest in Nuclear Technology. Results on g(r) are calculated from our MD trajectories and showed in comparison to the experimental results of Waseda.

![Graph 1](Lithium g(r) calculated (circles) compared with experimental results (triangles) at T= 460 and 520K. (Bottom) Lead g(r) calculated (circles) compared with experimental results (triangles) temperature ranging from T = 610K to T=1170K. In both cases a perfect agreement MD simulation – experiment in the radial distribution of the liquid phase is obtained.)

Fig. 3. (Top) Lithium g(r) calculated (circles) compared with experimental results (triangles) at T= 460 and 520K. (Bottom) Lead g(r) calculated (circles) compared with experimental results (triangles) temperature ranging from T = 610K to T=1170K. In both cases a perfect agreement MD simulation – experiment in the radial distribution of the liquid phase is obtained.

![Graph 2](Fig. 5. (top) Heat capacity, C_p, in J/mole-K, for solid Pb from MD simulations (squares) and experimental values (triangles) calculated in a MD run. The jump at 600K matches with the solid-liquid phase transition. (bottom). Heat capacity, C_p, in J/mole-K, for liquid lead and lithium from MD simulations (squares and triangles) compared with experimental values (circles and inverted triangles).)

IV.C. Study Of Thermodynamical Properties

Thermodynamic properties of liquid metals are the base of their industrial applications.

Heat capacity at constant volume, C_v, can be calculated once the system is in equilibrium from energy fluctuations as:

\[
C_v = \frac{1}{k_B T^2} \left( \langle E^2 \rangle - \langle E \rangle^2 \right)
\]

But experimental heat capacity values are usually measured at constant pressure, C_p. These two quantities
are related by the well known relation \( C_p = CV_T \frac{\partial C_p}{\partial T} \), where \( \alpha \) is the coefficient of thermal expansion and \( \beta_T \) is the isothermal compressibility. If we calculate the enthalpy of the system, defined as \( H = U + pV \) where \( U \) is the internal energy of the system, \( p \) is the pressure at the boundary of the system and its environment, and \( V \) is the volume of the system, then we can easily calculate \( C_p \).

\[
C_p = \left( \frac{\partial H}{\partial T} \right)_p
\]  

(3)

Calculated heat capacity, \( C_p \), gives good agreement with the expected values reported by Gurvich \(^{20}\) and Ohse \(^{21}\). Moreover, we can also calculate volume and enthalpy change at melting, \( \Delta V \) and \( \Delta H \) respectively, and compare with the proper experimental values \(^{21-22}\). In the case of lead, values agree fairly well with the experiment. Volume change in our simulations is about a 3.8% while experimentally is expected about 3.6%. In addition, the change in enthalpy (heating) is 5.5 kJ/mole while the experimental value is 4.8 kJ/mole. The result depends on the way we arrive to the final state, i.e., heating or cooling. Cooling the sample from a higher temperature down to the final one the values are: \( \Delta H = 5.4 \) kJ/mole and \( \Delta V = 2.5% \). For lithium, results depend more on the simulation size. Volume change in our simulations is about a 10.0% while the experimental one is 1.6%. The change in enthalpy is (heating) 4.5 kJ/mole while the experimental value is 3.0 kJ/mole. In cooling mode, the results are: \( \Delta H = 4.5 \) kJ/mole and \( \Delta V = 6.5% \).

V. CONCLUSIONS

Classical Molecular Dynamics simulations via EAM potentials have showed to be a powerful tool to simulate and understand liquid metals and alloys, in our particular case, lead and lithium. Our results prove the validity of these potentials and provide useful structural and thermodynamical data in conditions of interest to Nuclear Fusion technology. Reported figures are in agreement with experimental results available in the literature. In addition, our work represents a base methodology for the extrapolation of liquid Pb and Li properties into regions of temperature and composition where direct experimental measurements either do not exist, or are not accessible. Moreover, we have tested that our particular choice constitutes a solid base for the development of a future cross PbLi potential.

ACKNOWLEDGMENTS

We are grateful to Professor D. Belaschenko for providing us with his lithium EAM potential and fruitful comments. We thank for computing resources in CESGA, Computer Centre of the Institute for Molecular Science. This work was funded by the Spanish National Project on Breeding Blanket Technologies TECNO_FUS through CONSOLIDER_INGENIO 2010 Programme.
