Abstract—Real time Tritium concentrations in air in two chemical forms, HT and HTO, coming from an ITER-like fusion reactor as source were coupled the European Centre Medium Range Weather Forecast (ECMWF) numerical model with the Lagrangian Atmospheric-particle dispersion model FLEXPART. This tool was analyzed in nominal tritium discharge operational reference and selected incidental conditions affecting the Western Mediterranean Basin during 45 days during summer 2010 together with surface “wind observations” or weather data based in real hourly observations of wind direction and velocity providing a real approximation of the tritium behavior after the release to the atmosphere from a fusion reactor. From comparison with NORMTRI - a code using climatologically sequences as input - over the same area, the real time results have demonstrated an apparent overestimation of the corresponding climatologically sequence of Tritium concentrations in air outputs, at several distances from the reactor. For this purpose two development patterns were established. The first one was following a cyclonic circulation over the Mediterranean Sea and the second one was based on the plume delivered over the Interior of the Iberian Peninsula and Continental Europe by another stabilized circulation corresponding to a High Pressure System. One of the important remaining activities defined then, was the qualification tool. In order to validate the model of ECMWF/FLEXPART we have developed of a new complete data base of tritium concentrations for the months from November 2010 to March 2011 and defined a new set of four patterns of HT transport in air, in each case using real boundary conditions: stationary to the North, stationary to the South, fast and very fast displacement. Finally the differences corresponding to those four early patterns (each one in assessments 1 and 2) has been analyzed in terms of the tuning of safety related issues and taking into account the primary phase of tritium modeling, from its discharge to the atmosphere to the deposition on the ground, will affect to the complete tritium

environmental pathway altering the chronic dose by absorption, reemission and ingestion both from elemental tritium, HT and from the oxide of tritium, HTO.

Keywords—component; Atmospheric Tritium; Tritiated cloud, HT and HTO wet depositions.

I. INTRODUCTION. EDES UNDER PENTA LEVEL 3 REQUIREMENTS FOR PRECAUTIONARY MEASURES TAKEN FROM NORMTRI. ECMWF/FLEXPART MODEL REQUIRED IN THE PRIMARY PHASE.

In order to validate ECMWF/FLEXPART model it has been determined, in routine conditions of ITER the Most Exposed Individual (MEI) remains under defined values in the PENTA protocol as precautionary measurements.

Figure 1. NORMTRI executed for ITER reactor HT/HTO effluents at 30 level in routine, has given EDE by contribution of exposure pathways (percentage of inhalation, percentage of ingestion; and percentage of inhalation due reemission).

In reference [1] Effective Dose (EDE) from a NORMTRI study case was shown at all radial distances the precautionary “Plan of Emergency at Tarragona (PENTA) measurements for confinement were not required, due doses are under the regulatory PENTA limits.

Figure 2. Some examples of EDE(Sv) for zones 0, I and II. [1,2]

Some examples of EDES (Sv) for zones 0,I and II [1,2] in the closest 30 km to the reactor were already presented. When we made the validation of the model ECMWF/FLEXPART with a new complete data base of tritium concentrations for November 2010 to March 2011 we used special air patterns for tritium transport from source at Vandellós to the atmosphere low levels in the boundary layer in form of “tritiated clouds” if elemental HT or tritiated water. The aim of this paper is to define the new tritium cloud patterns and their consequences. For this purpose some particular examples will be presented and later compared. Concerning source term we assume major concentration activity of the tritiated species should be in the very low levels. Therefore we have selected 10, 30 and 60 meters for obtaining ECMWF/FLEXPART products of the emission release of tritium (when in continuous displacement in the boundary layer) [1]. The source term is placed in Vandellós, this is considered the point of release in routine. Fictitious exaggerated tritium sources of about 2.7 mg of tritium per event-day (~ 25 Ci/event-d) in HT form (e.g. emitted 3.65 mg of HT) or 0.27 mg (~ 2.5 Ci/event-d) of tritium per event-day in HTO (e.g. emitted: 1.8 mg of HTO) [4]. The dispersion of atmospheric tritium can be very different, as a function of the water vapor tritiated clouds development and movement (stratified or convective, horizontal or with vertical ascendant or descendent air currents).

I. EXAMPLE OF MEDITERRANEAN CASE 17 MARCH 2011

A. Real time evolution of HT by ECMWF/FLEXPART products

The transport of elemental tritium gas from source to the environment and by the atmosphere has been presented in four steps and different places, from Tortosa Canyon to the South of Balearic Islands, during the 17th and 18th of March 2011

(figure 3) with the corresponding real time evolution of HT by ECMWF/FLEXPART products [5].

Figure 3. Daily evolution of HT cloud/plume at 10 m from reactor over the Mediterranean Sea. During 24 hours, the displacement of elemental tritium gas in four steps and different places from Tortosa Canyon to the South of Balearic Islands.

Forecast HT clouds valid on the 18th of March 2011 by midnight can be observed at the South of the Balearic Islands (and North of Algiers). However in order to make comparison we just look for behaviour in PENTA Zones and around 120-130 km

Figure 4. Variable atmospheric HT cloud/plume transport at three levels at 10 m, 30 m and 60 m from reactor to 130 km downwind distance. Differences in the first 80 Km. Values over 1E+5 in the first 10 Km for the two lower levels.

Variable atmospheric HT cloud/plume transport is different at the 3 levels at 10 m, 30 m and 60 m in the first 80 Km. Concentration values are over 1E+5 just in the first 10 Km for the two lower levels. For downwind distances major than 80 km a lineal decrease of concentrations is observed in a similar fashion for all levels.

B. HT and HTO forecast evolution in short range, from 3 to 24 hours

Figure 5. Short range forecast evolution of atmospheric HT cloud/plume at 10m, 30m and 60 over the Mediterranean Sea. After 6 hours no significant differences forecasted between levels.

Initial evolution shows major concentrations for HT at 10 m (red line). The similarities in the short range forecast evolution of atmospheric HT cloud/plume at 10m, 30m and 60 m after 6 hours over the Mediterranean Sea is clear in the figure 5. Slightly logical differences for HT at 60 m (minor in the afternoon and by night).

Making systematic analysis of the complete data base, it leads to the requirement of stabilizing a set of threshold in the key parameters (mainly concentration and wind velocity) that allows representing a set of patterns in both sceneries: Mediterranean and Interior. Even they are slightly different, we introduce just Mediterranean Sea cloud Patterns of HT and finally we present another example for the interior case in order to compare them.

II. MEDITERRANEAN PATTERNS OF HT

After the analysis of the 6 month data base of real time ECMWF/FLEXPART tritium dispersion products it can be defined a set of patters coming from a particular source term in a selected plant location. We are looking for both the selection of tritiated cloud patterns in our data base and later a "possible" optimization of the Plant location.

A. Stationary Plume to North

After the analysis of the 6 month data base of real time ECMWF/FLEXPART tritium dispersion products it can be defined a conceptual stationary plume, when it can be transported downwind from source to less than around 100 km. When clouds are moving to the North of Vandellós, the atmospheric tritium can diminish 3 orders of magnitude, e.g. from $1\text{E}+6$ to $1\text{E}+3$ (Bq/m^3). This reduction can be chaotic. Wind speed corresponds to light (from the South) winds (e.g. velocity under 1, 5 m/s or around 5 km/h)

B. Stationary Plume to South

A stationary (or quasi-stationary) plume when moving to the South of Vandellós concentrations of atmospheric tritium can decrease by 3 orders of magnitude, e.g. from $1\text{E}+6$ to $1\text{E}+3$ (Bq/m^3). This reduction can be linear in Sea and chaotic by the interior (due orography e.g. Karman vortex, and other effects). Wind speed corresponds to light (from the North) winds (e.g. velocity under 5, 5 m/s). In the figure 6 variables HT cloud/plume at 10 m, 30 m and 60 m from reactor to around 50 km downwind distance and their corresponding lineal concentrations, in Bq/m^3 can be observed over the Mediterranean Sea.

Figure 6. Variable HT cloud/plume at 10m, 30m and 60 m from reactor to 50 km downwind distance and their corresponding lineal concentrations

C. Fast displacement Plume

Fast displacement plume when moving from Vandellós concentrations of atmospheric tritium can decrease even 4 orders of magnitude, e.g from $1\text{E}+6$ to $1\text{E}+2$ (Bq/m^3). This reduction can be quasi-linear in Sea (and "flow dependant" by the interior). Wind speed corresponds to moderate winds (e.g. velocity under around 15 m/s) therefore a larger displacement is foreseen. In the figure 7 variables HT cloud/plume at 10 m, 30 m and 60 m from reactor to around 130 km downwind distance and their corresponding lineal concentrations, in Bq/m^3 can be observed over the Mediterranean Sea.

Figure 7. HT cloud/plume at 10m, 30m and 60 m from reactor to 130 km downwind distance and their corresponding lineal concentrations, around $1\text{E}+5$ Bq/m^3

TABLE I. PROPOSED DESIGN TRITIUM IN AIR PATTERS IN MEDITERRANEUM

Pattern	Transport plume distance (Km)	Magnitud order range HT (Bq/m ³)	Tendency HT reduction	Observed 10m wind (km/h)
A-Stationary Plume to North	0 < R < 100 km Local to mesoscale	6-3	Caotic fashion reduction	CALM OR VERY LIGHT 0 < v < 5 km/h
B-Stationary plume to the South	0 < R < 100 Km Mesoscale transport	3-6	No Reduction (& orographic effects just in coast)	LIGHT 0 < v < 20 km/h
C-Fast displacement plume+ Vortex by orography	100 < R < 200 Km Large transport distance (in mesoscale)	6-2	Quasi lineal reduction	MODERATE 20 < v < 50 Km/h
D-Very fast displacement Plume	R > 240 Km Very Large transport distance (to synoptic)	6-2	Continuos reduction	STRONG 50 < v < 100 Km/h

D. Very Fast displacement Plume

Very Fast displacement plume when moving from Vandellós Plant concentrations of atmospheric tritium can diminish even 4 orders of magnitude, e.g. from $1\text{E}+6$ to $1\text{E}+2$ (Bq/m³). This continues reduction corresponds to the strong winds (at least greater than 25 mph or 15 m/s)

Table I summarized proposed defined tritium in air defined patterns in the Mediterranean Sea. Other different tuned features may be observed in the interior. To have the overview of all possibilities, in the next points, we present a particularization of two cases, one Mediterranean Sea (corresponding to the 17th of March 2011) and the second one over the interior and corresponding to the 15th of March). Finally we can compare both scenarios and assessments for conclusion on differences.

III. EXAMPLE OF INTERIOR CASE 15 MARCH 2011 WITH PRECIPITATION

A. Real time evolution of HT by ECMWF/FLEXPART products

The transport of elemental tritium gas from source to the environment and by the atmosphere has been presented in four steps and different places, from Vandellós to the interior of Aragón and in displacement to the North and again coming back to the coast, during the 15th and 16th of March 2011 (figure 3) with the corresponding real time evolution of HT by ECMWF/FLEXPART products

Figure 8. Daily evolution of HT cloud/plume at 10 m from reactor over the Interior of the Iberian Peninsula. During 24 hours, the displacement of

elemental tritium gas in four steps and different places from Aragón back to Catalanian coast.

Forecast HT clouds valid on the 16th of March 2011 by midnight can be observed in PENTA Zones and around 120 km.

Figure 9. Caotic/different atmospheric HT cloud/plume transport at three levels at 10 m, 30 m and 60 m from reactor to 120 km downwind distance. Differences in levels at all distances. Values over $1\text{E}+5$ in the first 20 Km

Different atmospheric HT cloud/plume transport at 3 levels in the boundary layer from source reactor to 120 km downwind distance. Differences in levels at all distances. Values over $1\text{E}+5$ in the first 20 Km for the 2 lower levels.

Figure 10. Short range forecast evolution of atmospheric HT cloud/plume at 10m, 30m and 60 m from reactor to more than 120 downwind distance over the Continent. After 6 hours significant differences between levels.

Variable atmospheric HT cloud/plume transport is very different at the 3 levels at 10 m, 30 m and 60 m in the 120 km range from source. Concentration values are over $1\text{E}+5$ just in the first 3-4 hours and around first 10 km for the two lower levels. No lineal decrease but caotic decrease of HT of concentrations is observed for all levels. (Fig. 9 and 10)

Figure 11. Variations of the wind velocity (m/s) during precipitation (mm) observed in the 15th of March 2011 (and first hour of the 14th) and after. Original data taken from AEMET (www.aemet.es) at Tortosa.

Figure 12. Remote sensing observations in March the 15th. In particular VIS and IR Meteosat Second Generation (MSG) images and reflectivity observed in the regional BCN radar along coast and interior of Catalunya and Aragón

The remote sensing observations are (both for satellite and radar) presented in the Figure 12. Reduction of concentration and transport of clouds (observed e.g. at 10 m in figures 9 and 10) in the interior of Catalonia corresponds to the area of precipitation (green dashed line) and wind reduction (red dotted line) forecasted for afternoon (see Figure 11). Radar reflectivity values corresponding to PPI on 16 March can be interpreted as an overestimation of surface PCP (mm) however its clear rainfall can lead to a cleaner atmosphere (concerning minor concentrations of HT in air). In satellite IR and VIS imagery at least two low centers can be detected as follows: one over the Gulf of Cadiz and the second one over Catalonia and South of France and the baroclinic band [14] is already extended up to the North of Africa. Radar reflectivity values corresponding to PPI on 16 March can be interpreted as an overestimation of surface PCP (mm) however its clear rainfall can lead to a cleaner atmosphere (concerning minor concentrations of HT in air).

IV. COMPARISON OF HT AND HTO OVER MEDITERRANEUM AND CONTINENTAL EUROPE

Figure 13. Early evolution comparison HT (red lines) and HTO (green lines) at 30 m from Mediterranean Sea to Continental Europe

The early evolution comparison HT (red lines) and HTO (green lines) at 30 m from Mediterranean Sea to Continental Europe is shown in figure 13. For both HT and HTO clouds over Mediterranean Basin and Continental Europe (CEUR) there are a lineal decreasing evolution. Forecast HT values are similar over Mediterranean Sea and CEUR (except by 9 UTC). On the contrary HTO values are minor in CEUR, may be due daily thermal oscillation; in other words an increasing in temperature (at noon and early afternoon) implies a decreasing HTO concentration (And also with HT).

Figure 14. Transport of HT (red lines) and HTO (green lines) at 30 m from Mediterranean Sea and Continental Europe from reactor localisation to downwind distances of 130 km. HT is reduced caotically at Continental Europe. Major values of HTO in CEUR for distances minor than 70 km

There are differences in the HT and HTO transport detected in the figure 14. In this case HTO is major in the Continental Europe than in the Mediterranean Sea in the first 70 Km. This particular exception may be due local effects as e.g. the lee orographic diffusion and/or stagnant by Pyrenees.

Figure 15. Corresponding evolution with the increase of wet deposition on the 15th of March, due cleaning effect of the PCP both in Wet deposition of HT and HTO from 18 to 30 hours increase. At 118 km the Wet deposition of HTO (red) is greater than HT Wet deposition

Also precipitation (observed by remote sensing) in March 15th play a role in cleaning air (and there is an increase of wet depositions forecast by the ECMWF/FLEXPART modeling system (Figure 15). Both Wet deposition of HT and HTO from 18 to 30 hours increase. At 118 km the Wet deposition of HTO (red) forecast is 3 orders of magnitude greater than HT. This can be associated to PCP, In particular visible and infrared Meteosat Second Generation (MSG) images and reflectivity observed in the regional BCN radar (figures 11 and 12) along coast and interior of Catalonia and Aragón at least at downwind distances around 120 km. In this area, maximum value of wet deposition $1,113 \text{ E}+13 (\text{Bq}/\text{m}^2)$ has been detected when observed maximum convective rainfall was 18 mm.

V. CONCLUSIONS

In routine conditions of ITER the Most Exposed Individual (MEI) remains under the defined values into the SP protocol PENTA as precautionary measurements. Therefore, in level 3, EDEs remain under the threshold values for a possible confinement in the exclusion zone (Zone 0). Further refinement may be based on Primary Phase outputs of ECMWF/FLEXPART.

For primary phase several patterns have been determined for tritium Clouds over the Mediterranean Basin (MED) and have been compared with other cases over continental Europe (CEUR).

ECMWF/FLEXPART HT and HTO clouds in air shown forecast concentrations with one order of magnitude of difference due source term original HT and HTO daily concentrations, correspondent to 1 gram of HT/year (and 0,1 gram HTO/year).

For both HT and HTO clouds over Mediterranean Basin and CEUR there are a lineal decreasing evolution (in all levels).

HT and HTO clouds over Mediterranean show a major transport by influence in diffusion, advection and/or convection. In the CEUR case the transport is limited to distances of less than 180 Km and it may be strongly influenced by the SP orography (Iberian System, Ebro Valley) and precipitations.

In any case variations of safety issues related due atmospheric thermal profile (e.g. at the low troposphere). Again expected real time MEI remains under controlled thresholds.
