ABSTRACT

Two multispectral maturity classifications for red soft-flesh peaches ('Kingcrest', 'Rubyrich' and 'Richlady' $n = 260$) are proposed and compared based on R (red) and R/IR (red divided by infrared) images obtained with a three CCD camera (800 nm, 675 nm and 450 nm). R/IR histograms were able to correct the effect of 3D shape on light reflectance and thus more Gaussian histograms were produced than R images. As fruits ripened, the R/IR histograms showed increasing levels of intensity. Reference measurements such as firmness and visible spectra also varied significantly as the fruit ripens, firmness decreased while reflectance at 680 nm increased (chlorophyll absorption peak).

1. Introduction

A major issue in designing vision systems for maturity assessment in fruits is the identification of the most relevant wavelengths for this goal. For monitoring ripening of peaches, reflectance at 450 nm and 680 nm can provide complementary information (Ruiz-Altisent et al., 2006). In the visible range, two areas have been addressed as the most important areas: 680 nm related to chlorophyll content, and 450 nm related to carotenoids content. Ruiz-Altisent et al. (2006) showed that both groups of pigments evolve independently for commercial peach varieties, also providing very different ranges of variation. Several research results have considered the chlorophyll band (Tu et al., 1995 cited by Lu (2004), Lu and Peng (2006)) or water absorbance band (McGlone et al., 1997 cited by Lu (2004)) as most relevant for maturity and firmness. Reflectance at 680 nm, related to chlorophyll content, presented the highest correlation with firmness in peach (Lu and Peng, 2006).

Differences can be found between (a) selecting narrow wavelengths as light sources while using standard panchromatic CCD cameras and (b) the use of panchromatic light with narrow filters for image acquisition. Thus, Tu et al. (1995) used He-Ne laser as a light source at 670 nm in peach and McGlone et al. (1997) used a diode laser at 864 nm as light source in kiwifruit. Instead, Lu and Peng (2006) made use of panchromatic light source.

Multispectral imaging is a technology originally developed for space-based imaging which may capture light from wavelengths beyond the visible light range, such as infrared, allowing the extraction of additional information that the human eye fails to capture. Multispectral imaging can be used to address external features such as ripening (Lu, 2004) and external defects (Diaz et al., 2000, 2004; Leemans and Destain, 2004; Kleynen et al., 2003; Mehl et al., 2004; Tao and Wen, 1999; Singh and Delwiche, 1994; Unay and Gosselin, 2006) with higher sensitivity in comparison to the ordinary RGB imaging (Gómez-Sanchís et al., 2008; Aleixos et al., 2002, 2007; Leemans et al., 2002; Kleynen et al., 2003).

RGB vision is a simplified case of multispectral imaging, where broad wavelength ranges are used. Aleixos et al. (2002) described an on-line image system for sorting oranges which used an RGB camera together with a 750 nm image. Defect regions were detected, and ripeness was estimated using Bayesian discriminant

algorithms. Laykin et al. (2002) used different algorithms that were applied to classify tomatoes employing RGB cameras, based on colour, defects and colour homogeneity. Also in tomatoes, Jahns et al. (2001) found that the dominating wavelength calculated from RGB images increases for increasing maturity, and that a significant negative correlation was found between firmness stage (elasticity modulus) and such dominant wavelength. Sugar content of lyokan orange was estimated ($R^2 = 0.6$) by means of neural networks by making use of colour, shape and roughness extracted from RGB images by Kondo et al. (2000).

When using several wavelengths for multispectral applications, the definition of ratios is a key target. Reflectance ratio 670 nm/800 nm was earlier shown to be a good maturity index for sorting yellow clingstone peaches (Delwiche et al., 1987). The main advantage of using ratios is the compensation of lighting changes and shape effects. The Normalized Difference Vegetation Index $NDVI = (R_{800} - R_{680}) / (R_{800} + R_{680})$ that uses two spectral bands, 680 and 800 nm, is a parameter that has shown to compensate such changes even for very large lighting changes, such as those registered under remote sensing. The NDVI can be used for chlorophyll content estimation in the image system presented by Vila et al. (2005).

The reference properties that are used as a base for comparison towards vision systems are mainly firmness and soluble solids content. Light backscattering has been related to firmness in several types of research in apple and peach. Lu (2004) used multispectral images at five spectral bands between 680 nm and 1060 nm, selected on literature review, to quantify light backscattering profiles of apple fruit for predicting firmness and soluble solids content. Using neural network methods, three different ratios that made use of four wavelengths gave the best predictions of fruit firmness. When only one ratio was used, 680 nm/940 nm gave the best firmness prediction. Tu et al. (1995) cited by Lu (2004) recorded reflectance images at 670 nm in peach. As firmness decreased, the red band histogram moved to the right, i.e. the intensity of the light reflected by the fruit increased as firmness decreased. McGlone et al. (1997) cited by Lu (2004) reported that the intensity of light emitted from the kiwifruit increased with decreasing firmness. Furthermore, Peng and Lu (2006) compared three mathematical models for scattering profiles in apples in order to improve firmness estimation. Qing et al. (2007) employed laser-induced backscattering light to predict soluble solids content and firmness in apples. Related to peach, Lu and Peng (2006) found that the backscattered light at 677 nm, characterised by four parameters extracted from its corresponding 'Lorentzian' profile, and also around 677 nm, had the highest correlation with peach firmness, using halogen lamp as light source. They also found that the region around one water absorption peak (950 nm) showed some correlation with firmness in some cultivars. Carlomagno et al. (2004) used a spectrograph in combination with a CCD camera analyzing the spectrum transmitted by peaches (detector positioned 120° with respect to the light) in the near infrared (730–900 nm). After denoising the signal, peaches were sorted based on their degree of ripeness, in terms of sugar content and firmness, with a minimum distance classifier method, obtaining 82.5% of correct classification with respect to the previous established classes.

Most recent developments concerning image analysis in the food industry have been shown by Du and Sun (2006) and Zheng et al. (2006). Applications of different colour spaces for food quality evaluation were reviewed. Du and Sun (2006) presented the recent advances in learning techniques for food quality evaluation based on computer vision. In the case of fruits, the statistics learning is employed for segmentation, feature extraction and defects classification: Bayesian classification process, Bayesian and linear discriminant analysis together with Mahalanobis distance classifiers (Kleynen et al., 2003; Diaz et al., 2000, 2004).

The main objective of the present work was to test the ability of multispectral images at two specific wavelengths (680 nm and 800 nm) to classify peaches into maturity categories and to compare such classification with regard to reference measurements such as firmness and reflectance at 680 nm achieved with a visible spectrometer. For this, these images were achieved with a three CCD camera using narrow bandwidth filters centred at 450 nm, 680 nm and 800 nm. The results corresponding to 680 nm and 800 nm are the ones presented in this work.

2. Materials and methods

2.1. Materials

Three cultivars of red soft-flesh peaches ('Kingcrest', 'RubyRich' and 'Richlady') were analyzed (260 fruits, 2 replicates per fruit, from a variety of maturity stages collected at harvest). Samples ($n = 30$ –40 fruits) were randomly selected from just-harvested fruits in a number of Murcia cooperatives, so that the whole maturity range was represented. Each sample was harvested on the same date, and was obtained from the same orchard. Samples were then sent to Madrid in refrigerated, isothermic boxes and after 12 h the temperature was increased (20°C) for 4–5 h, and the fruit was then ready for experimentation.

2.2. Reference and multispectral measurements

Non-destructive reference tests (contact firmness and reflectance spectrometry) and images acquisition were applied to 100% of the fruits, while destructive reference tests (Magness-Taylor firmness and soluble solids content SSC) were carried out on 75% of fruits. Reference tests were used to compare with the classifications based on the images obtained with the multispectral system. All measurements were carried out on both sides of the fruit (the most coloured side 'blush' and the opposite side 'ground'). Reference parameters were measured in the following order:

Contact firmness. Measured by means of Impactor response, the maximum impact acceleration (m/s^2) and duration (ms) were measured using the 'LPF-Lateral Impact Sensor 2.0' furnished with a piezoelectric accelerometer ENDEVCO model 256-10 (ENDEVCO, SAN JUAN CAPISTRANO, CA 92675 USA); which was adapted for on-line use by Garcia-Ramos et al. (2003). Measurements were carried out in triplicate on each side of the fruit samples.

Optical reflectance. Visible relative reflectance spectra were obtained with a portable spectrophotometer Minolta CM-50i (Konica Minolta Sensing, Inc., Japan), 450–700 nm, at 30-nm intervals. Selected wavelength values at 450 nm (R_{450}) and at 680 nm (R_{680}) were used as a reference with regard to multispectral information. Two measurements were taken on each fruit, one on each side.

Firmness. Maximum penetration force, Magness-Taylor (firmness), in N, and force/deformation ratio (hardness), in N/mm, were measured using a force/deformation resistance meter, with an 8-mm diameter rod, at a deformation rate of 20 mm/min using a Texture Analyzer XT2 (Stable Micro Systems Ltd., Godalming, UK). Measurements were taken on both sides of the fruit.

Soluble solids SS, measured in $^\circ\text{Brix}$, on a few drops of juice with a digital refractometer ATAGO PR-101 (ATAGO CO., LTD, USA). SS are correlated with the sweetness of peaches and basically consist of sucrose, glucose and fructose. The SS content was measured on both sides of each fruit.

Spectral imaging. The imaging system consisted of a framegrabber, National Instruments[®], and a three CCD custom camera, DuncanTech/Redlake MS-3100[®] (Redlake Inc., USA) with three band-pass filters centred at 800 nm Infrared (IR), 675 nm Red (R) and 450 nm Blue (B), with a bandwidth of 20 nm. The selection of these

spectral bands was based on the previous research (Ruiz-Altisent et al., 2006) and also on several optical indices extracted from the literature (Zude, 2003; Merzlyak et al., 2003; Delwiche et al., 1987).

The light source was provided by six 100 W halogen lamps.

Statistical analysis. The reference measurements were compared with the classifications based on the histograms of the images (Section 2.3.). One image was acquired from each side of the fruit. Non-supervised (Ward) classifications of fruits were carried out, made on both the individual varieties and the pooled samples. ANOVA was applied to the reference parameters and to the data extracted from the image analysis. The analysis of the images and data (Ward classification algorithm, ANOVA, regressions) was carried out using Matlab® (version 7.0; Math Works, Inc., USA) and Statistica® (version 6, StatSoft, Inc., Tulsa, Oklahoma, USA).

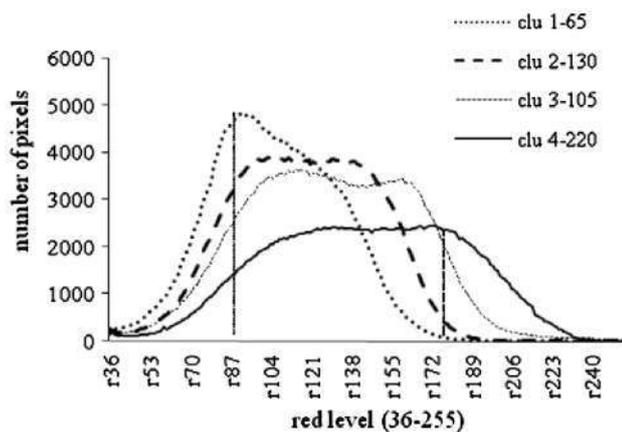

Fig. 1. Average red histogram for each cluster with the number of fruits for each. Vertical lines indicate the range of largest variation of the average histograms. From left to right, cluster 1, cluster 2, cluster 3 and cluster 4 average histograms. (Increasing maturity stage from 1 to 4).

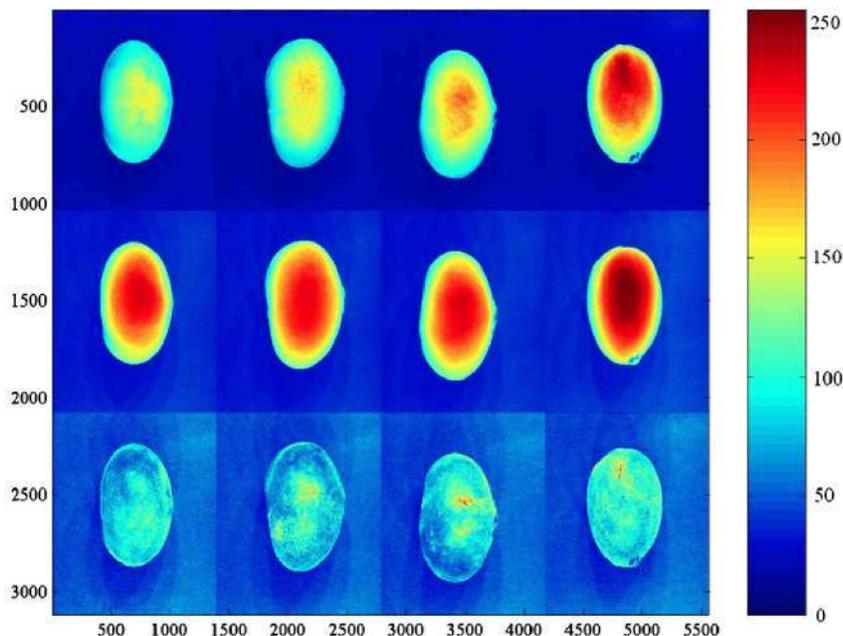

Fig. 2. Representation of the four centroid peaches belonging to each non-supervised classification. From left to right, cluster 1, cluster 2, cluster 3 and cluster 4 representative peaches (increasing maturity stage). First line corresponds to red channel, second to infrared and third to blue. Vertical colour bar represents intensity level of the images from 0 to 256. *x* and *y* axes represent the number of pixels of the images. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

2.3. Image analysis. Non-supervised classifications based on histograms

Two non-supervised classifications based on the Ward method (Ward, 1963) were applied and compared to each other and to the reference measurements. Both classifications were applied on the histograms extracted from the region of interest, *i.e.* the skin of the peach. Ward method is a step by step agglomerative method that minimizes the intra variance of a group or cluster. Therefore, a cluster is a group of samples with similar characteristics. The Ward method finds at each step these two clusters whose pooling gives the minimum increase in the within group sum of squares. The Euclidean distance between each datum and the corresponding centroid of the group was used to calculate such sum of squares. In the present work, two images were acquired per fruit, one from each side. The classifications were applied to all images (*i.e.* two images per fruit were acquired considering blush and ground colour sides; 260 fruits, 520 images). By studying the resulting dendrogram (not shown) with linkage distances between clusters, four clusters were considered in both non-supervised classifications presented. Once all the histograms for the four cultivars were grouped into the four clusters, the average histogram was calculated for each cluster.

The first classification considered the red channel images and grey levels ranging from 36 to 255, which corresponded to the values above the segmentation threshold of fruit with regard to the background.

The second classification employed the histograms of the Red/InfraRed images, corresponding to the peach. Previously the fruit was segmented from the background, by employing the Infrared images as threshold (under the particular illumination and acquisition conditions, fruits always corresponded to grey levels higher than 55 in every case). Internal validation of the Red/InfraRed images classification was performed by means of the calculus of the Euclidean distance between each anonymous histogram and the corresponding average of the four clusters. Each histogram was assigned to the cluster whose distance is the minimum of the four clusters.

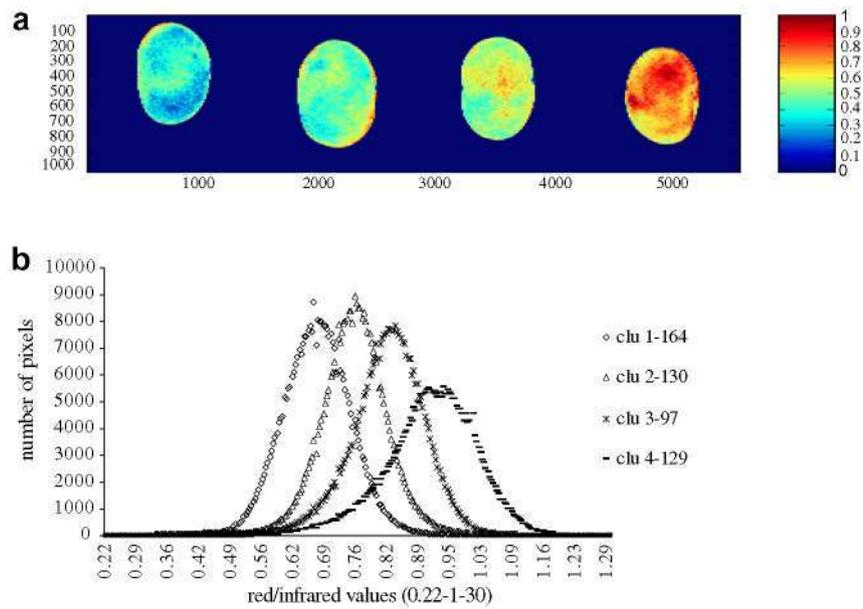

Fig. 3. (a) Red/infrared images for the four centroid peaches. Vertical colour bar represents intensity level from 0 to 1 (scaled images); x and y axes represent the number of pixels of the images. (b) The averaged histograms of the red/infrared clusters. The number of fruits is indicated. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Table 1

The number of observations per cluster and cultivar based on Red/InfraRed classification.

Cultivar	Cluster 1	Cluster 2	Cluster 3	Cluster 4	Total
Richlady	138	79	20	3	240
Kingcrest	2	7	19	32	60
Unknown	24	39	41	36	140
RubyRich	-	5	17	58	80
Total	164	130	97	129	520

3. Results and discussion

Three main results are presented in this study: classification based on red histograms, classification based on relative red/infra-

red histograms and comparison of multispectral categories with regard to reference parameters such as firmness.

3.1. Non-supervised classification based on red histograms

The red channel (R) includes a chlorophyll absorption peak at 675 nm. As fruits ripen, reflection increased in this band due to the chlorophyll degradation and so the histogram shifted toward brighter levels. These results are congruent with those of Tu et al. (1995). More recently, Lu and Peng (2006) indicated the feasibility of using backscattered light at 677 nm to classify firmness. It is important to note that these authors have focused on local backscattering, while the present study made use of direct lighting and global fruit imaging, which are simpler to incorporate as an on-line procedure.

Table 2

The number of fruits in each cluster of the camera classifications (considering pooled data for blush and ground). All fruits together $n = 260$. Classifications based on red/infrared histograms.

Ground color side	Blush area side				Total fruits and percentage
	Cluster 1	Cluster 2	Cluster 3	Cluster 4	
Cluster 1	54	13			67 (81%)
Cluster 2	32	28	4		64 (44%)
Cluster 3	9	16	17	2	44 (40%)
Cluster 4	2	9	32	42	85 (49%)
Total of fruits and its percentage of classification agreement	97 (56%)	66 (42%)	53 (32%)	44 (98%)	260

Table 3

Comparison of ANOVA results based on red and red/infrared clustering for the reference parameters.

		Soluble solids ($^{\circ}$ Brix)	Impact acceleration, (m/s^2)	Impact time (ms)	MT firmness (N)	Force/Deformation (N/mm)	R 450	R680
Red	F (Fisher)	2.6	18.3	44.8	46.8	51,1	6,3	257
Red/infrared		3.9	20.3	78.4	85	96,4	9,6	466
Red	p level	0.05	0	0	0	0	0	0
Red/infrared		0.01	0	0	0	0	0	0

Three or four naturally grouped clusters could be recognized in the fruit samples on the R image histograms using the Ward method (blush and ground color sides). The clusters were numbered from the lowest to the highest mode on the histograms, reflecting increasing maturity levels (i.e. cluster 1 the unripest, cluster 4 the ripest).

Fig. 1 represents the average histogram for each cluster numbered based on expected maturity level. Histograms moved towards higher intensity values for increasing maturity stage. Histograms showed large differences between clusters in the range between 90 and 180 intensity levels. The number of fruits belonging to each cluster is indicated in the figure. A large number ($n = 220$) of fruits were included in the so-called ripest stage.

Fig. 2 shows the images corresponding to the most representative ('centroid') peach for each R cluster and for each channel, red (675 nm), infrared (800 nm) and blue (450 nm). R (first line) and IR images (second line) showed the effect of the shape of the fruit on the global intensity level recorded by the camera; reflectance was higher at the center of the fruit, which was closer and orthogonal to the camera. The blue channel provided very little information compared to the other channels.

3.2. Combination of red (R) and infrared (IR) images for classifications purposes

In order to compensate for the geometrical effect of the fruit, the R/IR ratio was computed and a new non-supervised classification of the R/IR image histogram (blush and ground color sides) was provided, and the classification computed following Ward method described in Section 2.3. Fig. 3 shows the 'centroid' fruit obtained by means of a rebuilt clustering process that makes use of R/IR images. The corresponding average histograms were more Gaussian as compared to those obtained with R histograms, that is to say the distortion of illumination was avoided.

The number of fruits that belonged to each cultivar and cluster within the R/IR classification is shown in Table 1. Most cultivars provided fruits for the whole set of maturity stages, only 'Rubyrich' lacked fruits for cluster 1.

In Table 2, a comparison of the agreement of the classifications of the fruits in each R/IR cluster based on the blush and ground color sides is made. Generally, all fruits were classified in the same or adjacent maturity clusters and thus there were a larger number of fruits around the principal diagonal.

In the present case, no relationship was found between multispectral classification and soluble solid content, which is detected by only one NIR band (800 nm), even though Carlomagno et al. (2004) reported promising results using NIR spectrometry centred on this band. This fact may be explained by the lower range of variability in commercial peaches produced in Murcia, Spain.

Regarding the internal validation of the R/IR classification by means of assignment of a histogram of an image to one of the four clusters whose Euclidean distance was the minimum, the result was that a high percentage of well-classified fruits was obtained, when comparing the observed classification to the predicted classification (90% of accordance).

3.3. Comparison of multispectral categories with regard to reference parameters

The most effective classification method (R or R/IR) was determined by comparing the ANOVA analyses of the results for R and R/IR clustering using the reference measurements as shown in Table 3. A major feature was the increase in F (Fisher) value for R/IR clusters as compared to R clusters for all the parameters tested: soluble solids, impact acceleration, impact duration, Magness-Taylor maximum penetration force, force/deformation ratio, reflec-

Table 4 Average values and standard deviations of different parameter per cultivar, cluster (Classification based on red/infrared images) and side of the fruit. Within lines, for each cultivar, means followed by the same letter are not significantly different by ANOVA Fisher LSD test ($p < 0.05$); different letters implies there is significant difference between means.

tance at 450 and at 680 nm. The classification capacity of images was improved by the use of relative R/IR images. Reflectance at 680 nm showed the highest F value in both classifications (466 and 257 for R/IR and R classifications, respectively). This is congruent with the fact that red images and also the relative R/IR images include the chlorophyll absorption peak at 675 nm.

In Table 4, a comparison of the average reference values (soluble solids content, impact acceleration, Magness-Taylor firmness and reflectance at 680 nm) for each R/IR cluster and cultivar is made. Considering the pool of the four cultivar samples, firmness and reflectance at 680 nm varied significantly (significant differences between means for p level below than 0.05) with increasing cluster number: firmness decreased while reflectance at 680 nm increased. Similar behaviour with respect to firmness and reflectance at 680 nm was found within each cultivar group except in the case of 'Rubyrich' samples where firmness parameters did not vary with cluster number, and in the case of 'Kingcrest' where variation in Magness-Taylor firmness was erratic for the ground color side. Soluble solids content did not appear to be related to the R/IR classification in any case, showing no significant variation between groups, in accordance with the low range of variability in observed reference values in °Brix (between 11 and 13 in averages).

Fig. 4a shows Magness-Taylor firmness vs. impact duration with each point corresponding to one side of the fruit, 420 observations in total. The coefficient of correlation between both measurements R was 0.79. The standard error of estimation is 8.5 N, being 13.7 N the standard error of the observed Magness-Taylor firmness in the whole population. A nonlinear relationship was found between Magness-Taylor firmness and Impact response. Such nonlinear behaviour has also been referred to in the literature (Diezma-Iglesias et al., 2006).

Firmness decreased for an increasing number of clusters (1–4): Magness-Taylor firmness for almost all fruits (82%) belonging to cluster 4 was less than 25 N while that for 87% of fruits from cluster 1 was larger than 25 N.

Fig. 4b shows the average visible reflectance spectrum (420–690 nm). In the interval between 630 nm and 690 nm, the average spectrum consistently increased with maturity cluster; this result is in accordance with the earlier results such as those reported by Ferrer et al. (2005) who also found higher reflectance values in the same range as in more mature peaches.

4. Conclusions

With the aim of classifying peaches at harvest into maturity levels, two multispectral camera classification procedures were established using red channel (red images, R) and a combination of red and infrared images (red divided by the corresponding infrared image, R/IR). The use of the R/IR ratio avoided the effect of fruit shape on light reflectance and thus improved the definition of multispectral maturity clusters. Both classification procedures (applied to the histograms of R and R/IR images, respectively) consistently showed increasing harvest maturity levels, from clusters 1 to 4, compared with firmness (which decreases with maturity level) and reflectance visible spectrum (which increased with maturity in the interval 420–690 nm). Image-based classification gave information similar to that obtained from the reflectance at 680 nm as measured with a portable spectrometer. Reflectance at 680 nm increased whereas firmness decreased, for increasing maturity levels from clusters 1 to 4, by considering all data together ($n = 420$ of three cultivars, 'Kingcrest', 'Rubyrich' and 'Richlady'). The image classification did not reflect variation in soluble solids content in accordance with the observed range of variability of the reference values in °Brix. In the near future, a combination (fusion) of non-destructive methods of standardizing firmness such as impact and multispectral image data, will improve the classification of peaches at harvest. Finally the nonlinear relationship between Magness-Taylor firmness and impact has been confirmed.

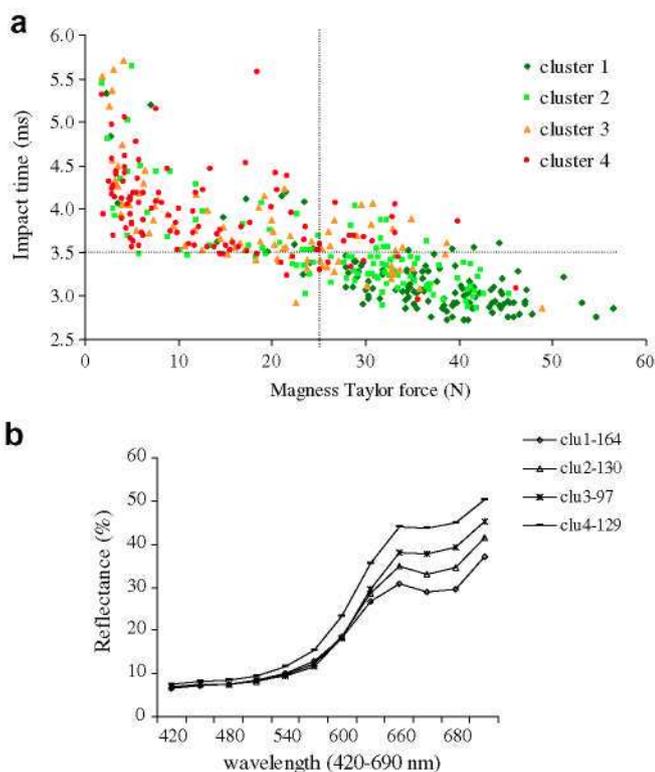

Fig. 4. (a) Magness-Taylor force (x axis) versus impact time (y axis). Each point corresponds to one side of the fruit, all measurements $n = 420$. (b) Average reflectance visible spectrum (Minolta) for each non supervised cluster of the camera (red/infrared images), $n = 520$. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)
