To date, crop models have been little used for characterising the types of cultivars suited to a changed climate, though simulations of altered management (e.g. sowing) are often reported. However, in neither case are model uncertainties evaluated at the same time.

Ensemble modelling can provide information on uncertainty in model outputs. Here, a probabilistic approach using multi-model ensembles is presented for evaluating the effectiveness of new crop cultivars under climate change. It comprises a unique combination of crop ensemble modelling with three other methodological elements illustrated for wheat: (i) ideotyping of wheat cultivars for future climates based on an agroclimatic indicator approach used for identifying shifts in risks to be avoided, (ii) impact response surface (IRS) analysis of current and new wheat cultivars under different CO_2 concentrations, and (iii) overlay of resultant IRSs for different time periods with joint probabilities of projected temperature and precipitation to evaluate changing risk.

This novel approach applies a subset of results from a systematic climate sensitivity analysis based on a large ensemble of over twenty wheat models (IRS1), and on agroclimatic indicator analyses with recently refined critical thresholds that suggest severe impacts of future climate change on yields of current wheat cultivars in Europe.

Applying the approach for different soil conditions and projected 2050s climate shows the potential of new cultivars with adjusted management to reduce risks of future climate-

induced crop stress. Results also underline the need for crop model improvements, new experimental data and co-innovation with stakeholders, to better evaluate adaptation options.
