Abstract

Facial expression recognition is a topic of interest both in industry and academia. Recent approaches to facial expression recognition are based on mapping expressions to low dimensional manifolds. In this paper we revisit various dimensionality reduction algorithms using a graph-based paradigm. We compare eight dimensionality reduction algorithms on a facial expression recognition task. For this task, experimental results show that although Linear Discriminant Analysis (LDA) is the simplest and oldest supervised approach, its results are comparable to more flexible recent algorithms. LDA, on the other hand, is much simpler to tune, since it only depends on one parameter.

1. Introduction

One of the open problems of computer science is to make computers that interact with humans in a natural way. A key element in natural human computer interaction is the recognition of human facial expressions. Recently, much effort is being devoted within the computer vision research community to processing video sequences and modeling dynamic facial expressions [2, 14]. One way to solve this problem is mapping facial expression to low dimensional manifolds exhibiting separable distributions for different expressions [2, 4, 9]. In this paper we compare the performance of eight graph-based dimensionality reduction algorithms on a facial expression recognition problem.

2. Face alignment and facial expression recognition

Face images are located and tracked at video frame rates using an efficient face alignment procedure [1]. The

Figure 1. Illumination rectified images.

tracker automatically crops the face and compensates illumination changes, as shown in Fig. 1, where the first row shows the original cropped images and the second row the corresponding illumination rectified ones. PCA projection of these sequences onto a 90-dimensional space¹ helps avoid the curse of dimensionality.

We aim to recognise Ekman's six prototypic facial expressions (joy, surprise, anger, sadness, fear, disgust). To do so we adopt a model-based approach for facial expression recognition. By tracking a set of 322 labeled image sequences of 92 subjects from the Cohn-Kanade data base [8], we build a user-and-illumination-independent global representation of all facial expressions. In this model, a face image is represented with a point in the 90-dimensional space of deformations. The variability of the classes of images associated to the prototypic facial expressions are represented by the Kohn-Kanade aligned images projected onto a lower dimensional subspace embedded in the 90-dimensional space of deformations, termed the *facial expression manifold*. In this paper we compare the performance of eight graph-based dimensionality reduction algorithms in the construction of the facial expression manifold.

Finally, images representing similar expressions are mapped to nearby points on the manifold. We use the nearest-neighbour probabilistic procedure introduced in [2], section 5, to combine the information provided by the incoming image sequence with the information

¹The dimension of this subspace was determined by *parallel analysis* [10].

represented in the expression manifold to estimate the posterior probability of a facial expression.

3. Graph-based Dimensionality Reduction

3.1. The Basic Idea

On the whole the graph-based dimensionality reduction algorithms reviewed here are all built on the basis of a simple relationship (c.f. [5]):

$$\sum_{i,j} \|\mathbf{x}_i - \mathbf{x}_j\|^2 W_{i,j} = 2\text{tr} X^\top L X, \quad (1)$$

where $\mathbf{x}_i \in \mathbb{R}^n, i = 1, \dots, N$, $X = (\mathbf{x}_1, \dots, \mathbf{x}_N)^\top$, W and L is the weight matrix and Laplacian matrix of a given graph respectively². Equation (1) represents the scatterness of the given feature vectors \mathbf{x}_i w.r.t. the given graph. For example, the early Locality Preserving Projection (LPP) algorithm [6] is unsupervised, which, via a linear projection P_{ULPP} , retains the neighborhood information obtained from high-dimensional data by choosing $W_{i,j} = 1$ when $\mathbf{x}_i \in \mathcal{N}(\mathbf{x}_j)$ or $\mathbf{x}_j \in \mathcal{N}(\mathbf{x}_i)$ ($\mathcal{N}(\mathbf{x})$ denotes the neighbourhood of \mathbf{x}) and $W_{i,j} = 0$ otherwise. The desired P_{ULPP} minimizes

$$\min_P \text{tr} P^\top X^\top L_{\text{ULPP}} X P \quad \text{s.t.} \quad P^\top X^\top D_{\text{ULPP}} X P = I,$$

where tr denotes the trace of a matrix. Later, a supervised version of LPP [7] is developed. The proposed graph G_{SLPP} has an edge between each pair of samples from different classes. Thus the desired projection will push samples of different classes away from each other and result in an increased Between Class Scatterness (BCS), i.e. P_{SLPP} solves the following optimization

$$\max_P \text{tr} P^\top X^\top L_{\text{SLPP}} X P \quad \text{s.t.} \quad P^\top X^\top D_{\text{SLPP}} X P = I.$$

3.2. PCA and LDA

The well-known Principal Component Analysis (PCA) and LDA algorithms may also be described in terms of (1) using a graph-view of the common covariance matrix,

$$\begin{aligned} X^\top \left(I - \frac{1}{N} \mathbf{1}\mathbf{1}^\top \right) X &= \frac{1}{N} \sum_{i=1}^N (\mathbf{x}_i - \bar{\mathbf{x}})(\mathbf{x}_i - \bar{\mathbf{x}})^\top \\ &= \sum_{i,j=1}^N W_{i,j} (\mathbf{x}_i - \mathbf{x}_j)(\mathbf{x}_i - \mathbf{x}_j)^\top, \end{aligned}$$

²A graph G has several associated matrices, weight matrix W whose elements in i th row and j th column, $W_{i,j}$ is the weight of the edge between \mathbf{x}_i and \mathbf{x}_j and is zero when there's no edge between the two vertices, D for a diagonal matrix $\text{diag}\{d_1, \dots, d_N\}$ where $d_i = \sum_{j=1}^N W_{i,j}$, and the Laplacian matrix $L = D - W$. For different graphs, different subscripts or superscripts are used.

where $W_{i,j} = \frac{1}{N}$. Inspired by this formulation, Local Fisher Discriminant Criterion (LFDC) [11] rephrases LDA and adds locality to the classical LDA algorithm by modifying the original weights,

$$\begin{aligned} S_w &= \frac{1}{2} \sum_{i=1}^N \sum_{j=1}^N B_{i,j} W_{i,j}^w (\mathbf{x}_i - \mathbf{x}_j)(\mathbf{x}_i - \mathbf{x}_j)^\top \\ S_b &= \frac{1}{2} \sum_{i=1}^N \sum_{j=1}^N B_{i,j} W_{i,j}^b (\mathbf{x}_i - \mathbf{x}_j)(\mathbf{x}_i - \mathbf{x}_j)^\top \end{aligned}$$

where

$$W_{i,j}^w = \begin{cases} \frac{1}{N_{y_i}} & y_i = y_j \\ 0 & \text{otherwise} \end{cases} \quad W_{i,j}^b = \begin{cases} \frac{1}{N} - \frac{1}{N_{y_i}} & y_i = y_j \\ \frac{1}{N} & \text{otherwise} \end{cases}$$

are the original weights for the within class and between class graphs implicitly used in LDA. LFDC imposes locality on these graphs by refraining the edges to only near samples, i.e. by defining B as a neighborhood matrix, that is, $B_{i,j} = 1$ iff \mathbf{x}_i and \mathbf{x}_j are neighbors to each other, otherwise $B_{i,j} = 0$.

3.3. MFA, DNE and LSDA

Marginal Factor Analysis (MFA) [12], Discriminant Neighborhood Embedding (DNE) [13] and Locality Sensitive Discriminant Analysis (LSDA) [3] all build two graphs from neighborhood relationships, one for Within Class Compactness (WCC), the other for BCS. MFA has one graph G_{MFA}^w whose edges are between each sample and its k_1 -nearest neighbors in the same class, the other G_{MFA}^b whose edges are between each sample and its k_2 -nearest neighbors in all other classes. It seeks the directions $\mathbf{v}_i, i = 1 \dots, d$ that maximizes

$$\frac{\mathbf{v}_i^\top X^\top L_{\text{MFA}}^b X \mathbf{v}_i}{\mathbf{v}_i^\top X^\top L_{\text{MFA}}^w X \mathbf{v}_i} \quad \text{s.t.} \quad \mathbf{v}_i^\top X^\top L_{\text{MFA}}^w X \mathbf{v}_j = \delta_{i,j},$$

where $\delta_{i,j}$ is the Kronecker's delta and $j = 1, \dots, i$. DNE, on the other hand, minimizes the difference,

$$\mathbf{v}_i^\top X^\top (L_{\text{MFA}}^w - L_{\text{MFA}}^b) X \mathbf{v}_i \quad \text{s.t.} \quad \mathbf{v}_i^\top \mathbf{v}_j = \delta_{i,j},$$

where $j = 1, \dots, i$. In [13], Zhang and et al. paraphrase their idea with negative weights for the between class edges. It's easily seen that their Laplacian matrix for the graph with negative weights is almost $L_{\text{DNE}}^w - L_{\text{DNE}}^b$, except the edge rules—in [13] there will be edges between each sample and its k nearest samples, with positive weight if they are in the same class, otherwise negative ones. LSDA goes a little further by explicitly introducing a balancing parameter $\alpha \in [0, 1]$, resulting in

$$\begin{aligned} \max_{\mathbf{v}_i} \quad & \sum_{i=1}^d \mathbf{v}_i^\top X^\top (\alpha L_{\text{MFA}}^b - (1 - \alpha) L_{\text{MFA}}^w) X \mathbf{v}_i \\ \text{s.t.} \quad & \mathbf{v}_i^\top X^\top W_w X \mathbf{v}_j = \delta_{i,j} \end{aligned}$$

Figure 2. A Comparison of DNE, MFA and LSDA

Figure 3. The expressions manifold in the PCA+LDA subspace (only the first 3 dimensions).

or equivalently

$$\begin{aligned} \max_{\mathbf{v}_i} \quad & \sum_{i=1}^d \mathbf{v}_i^\top X^\top (\alpha L_{\text{MFA}}^b + (1 - \alpha) W_{\text{MFA}}^w) X \mathbf{v}_i \\ \text{s.t.} \quad & \mathbf{v}_i^\top X^\top W_w X \mathbf{v}_j = \delta_{i,j} \end{aligned}$$

To have a clearer view of these algorithms, Fig. 2 shows a simple case: the ellipse-like curve shows the pair of WCC and BCS when a unit vector rotates in the plane. The MFA seeks for the line that intersects the ellipse with maximum slope (the blue dashed line). The DNE seeks for the line with slope 1 that intersects the ellipse and has largest intercept on y -axis (the red dash-dot line). Different choices of α for LSDA yield different lines that is just tangent to the upper half of the ellipse. If the embedding space is 1-dimensional, LSDA is best since with enough trial of α cross validation will ultimately picks a no worse projection than DNE and MFA. But it's not true for higher-dimensional embeddings, since α is constant.

4. Experiments

In this section we compare the dimensionality reduction algorithms described above for the facial expression recognition task introduced in section 2. For our comparison we used the Cohn-Kanade database, that was also used for building the expression manifold.

To estimate the recognition rate, we employ a leave-one-subject-out strategy for cross validation, in which sequences of each subject are tested against the model trained with all other sequences. Since all sequences in the database start with a neutral expression, we have verified that it is better to train the dimensionality reduction procedure with the last 6 images of each sequence. Hence during the training for each fold, there are more than 1500 images.

Cross validation also helps to obtain a model trained with the best suitable configuration parameters. There are several parameters that controls the behavior of the algorithms introduced in Sec. 3. Also the classifier has three parameters: a smoothing parameter h , a neighbourhood size k and η to avoid the veto effect [2]. In the experiments, we search for best combination of the discriminant projection model and the classifier. For the classifier, η is manually set to 0.3, h takes values in $\{1/6, 0.2, 0.3, 0.4, 0.5, 0.6, 0.8, 1\}$ and k in $\{21, 23, \dots, 59\}$.

In Tab. 1, we display the results of the experiments conducted. Unsupervised algorithms such as PCA and UnsLPP lead to low recognition rates. In our feature space, images that are close to each other will not necessarily be of the same expression. On the contrary, they are more likely to be different expressions of the same subject. Thus, for building a good discriminating projection, it is not adequate to preserve a neighborhood based on pixel-level distance as UnsLPP does.

Surprisingly, LDA yields a competent recognition rate compared with other complicated algorithms, although it is the oldest and simplest supervised procedure. As shown in Fig. 3, the expression manifold contains one single cluster for each type of expression. Introducing locality into LDA, as LFDC does, slightly enhances the performance. The LFDC model in Tab. 1 is trained with a neighborhood size 150, best in $\{30, 40, 50, 80, 100, 150, 200\}$.

MFA is able to give result comparable to those of LDA when k_1 and k_2 are sufficiently large. We set $k_1 = k_2 = 100$ to obtain the reported result. Actually, a slightly worse result is obtained when setting $k_1 = k_2 = 50$ or $150, 200$. LSDA is more flexible than DNE since it is feasible to tune α and balance the BCS and WCC. The configuration for LSDA in Tab. 1

Projection	PCA	LDA	SLPP	ULPP	LFDC	MFA	DNE	LSDA
Rate	76%	86%	85%	50%	86%	86%	84%	86%
Dimension	50	5	5	15	7	6	11	9
k	43	31	33	15	35	43	27	31
h	1/6	0.2	1/6	0.2	0.3	0.6	1/6	0.2

Table 1. Recognition rate for all eight dimensionality reduction approaches.

is $k_1 = 100, k_2 = 100$ and $\alpha = 0$. It's interesting to note that the recognition rate actually decreases as α increases to 1, which means it's important to minimize WCC instead of maximizing BCS. The DNE projection in Tab. 1 is trained with a neighborhood size 13.

These graph-based dimensionality reduction algorithms give us more room for tuning. Even though the data for facial expression recognition do not conform to the clustering assumption which might be necessary for designing them, they do work fine, perhaps even finer than the traditional algorithms. But on the other hand, with more choices of parameters, it takes much more time than LDA to find a proper setting. It is even possible to get a higher recognition rate given more time to search for other settings of LSDA. But anyway, now it might be close to the limit the linear methods could get to.

5. Conclusion

In this paper have revisited several dimensionality reduction algorithms and compared their performance on a facial expression recognition task. Unsupervised approaches like PCA and UnsLPP have the lowest recognition rates, since nearby images in our feature space are more likely to be different expressions of the same subject. Supervised approaches, on the other hand, achieve the best performance. LDA represents the best compromise between performance and complexity. For this problem, the WCC measure dominates BCS and consequently LSDA performs better than DNE. LSDA is the algorithm with the best recognition rate.

Also, these experiments show that, for appearance-based facial expression recognition tasks, we must build a large enough neighborhood for each sample, since the distance information in the feature space actually does not help in building discriminant projection and thus a small neighborhood would be misleading.
